Abstract
Abstractions are important in specifying and proving properties of complex systems. To prove that a given automaton implements an abstract specification automaton, one must first find the correct abstraction relation between the states of the automata, and then show that this relation is preserved by all corresponding action sequences of the two automata. This paper describes tool support based on the PVS theorem prover that can help users accomplish the second task, in other words, in proving a candidate abstraction relation correct. This tool support relies on a clean and uniform technique for defining abstraction properties relating automata that uses library theories for defining abstraction relations and templates for specifying automata and abstraction theorems. The paper then describes how the templates and theories allow development of generic, high level PVS strategies that aid in the mechanization of abstraction proofs. These strategies first set up the standard subgoals for the abstraction proofs and then execute the standard initial proof steps for these subgoals, thus making the process of proving abstraction properties in PVS more automated. With suitable supplementary strategies to implement the “natural” proof steps needed to complete the proofs of any of the standard subgoals remaining to be proved, the abstraction proof strategies can form part of a set of mechanized proof steps that can be used interactively to translate high level proof sketches into PVS proofs. Using timed I/O automata examples taken from the literature, this paper illustrates use of the templates, theories, and strategies described to specify and prove two types of abstraction property: refinement and forward simulation.

Keywords: Mechanical Theorem Proving, Strategies, I/O Automata, Abstraction, Refinement, Forward Simulation.

1 Introduction

Abstractions are essential for applying formal methods to verify certain classes of properties of complex systems, such as properties of system executions. Given an automaton $C$, suppose we wish to verify that every visible behavior—i.e., trace—of $C$ satisfies some property $P$. An effective way of doing this is to model the property $P$ itself as the set of traces of an abstract automaton $A$, and then to show that the set of traces of $C$ is a subset of the set of traces of $A$. This method generalizes to using not just a single abstraction, as above, but many levels of abstraction between the concrete, possibly complex implementation of a system and its abstract specification. A systematic way of showing trace inclusion—that every trace of automaton $C$ is included in the set of traces of another automaton $A$—is to show that there exists an abstraction relation between the states of the two automata. Thus the creation of a specification automaton $A$ for the property $P$ can reduce the problem of verifying that $P$ holds for $C$ to proving an abstraction relation between $C$ and $A$.

There are several possible abstraction relations between two automata, homomorphism, refinement, forward simulation, backward simulation, and so on. Forward-and-backward simulation relations are complete with respect to trace properties of I/O automata [9], and therefore they are powerful tools for automata-based verification. In this paper, we present a clean and uniform way of specifying abstraction properties relating pairs of automata in the PVS theorem prover [17] and describe how our specifications allow us to provide a set of generic strategies that aid users in proving abstraction properties while minimizing the necessary interaction with the prover.

One approach to supporting generic strategies in tactic-based provers such as PVS is to adhere to specification templates that provide a uniform organization for specifications and properties upon which strategies can rely. This approach has been used in TAME (Timed Automata Modeling Environment) [2,3], an interface which is designed to simplify proving properties of automata in PVS. Until now, TAME proof support has been aimed at properties of a single automaton—mainly state and transition invariants for (both timed and untimed) I/O automata, though TAME does include minimal strategy support for proofs of properties of execution sequences of I/O automata. All of TAME’s proof support is aimed at supplying “natural” proof steps that users can employ in checking high level hand proofs of properties of automata that are specified following the TAME automaton template.

One longstanding goal for TAME has been to extend its proof support to include proofs of refinement, simulation, and other abstraction properties involving two automata. This goal includes the ability to reuse established specifications and invariants of two automata in defining and proving an ab-
straction relation between them. A second part of this goal is that the new proof support for abstraction properties should be generic in the same way as TAME support for invariant proofs: that is, there should be a fixed set of TAME proof steps, supported by PVS strategies, that can be applied to proofs of abstraction properties without being tailored to a specific pair of automata. Finally, this goal includes making the new TAME proof steps “natural”—that is, they should provide a straightforward representation in PVS of the high level proof steps used in hand proofs of abstraction properties. The theory interpretation feature [15] in the latest version of PVS (PVS Version 3), combined with some recent enhancements in PVS 3.2, makes it possible to accomplish these goals.

In previous work [12], we outlined our plan for taking advantage of these new PVS features in specifying abstraction properties and developing uniform PVS strategies for proofs of these properties. In this paper, we describe how specification and proofs of abstraction relations between two automata can now in fact be accomplished in TAME, and illustrate these new capabilities on examples. Section 2 reviews automata models and TAME’s support for invariant proofs; discusses the past problem with designing TAME support for abstraction proofs; and shows how with PVS 3.2, methods similar to those used in TAME support for invariant proofs can now be used to provide TAME support for abstraction proofs. Section 3 describes the strategies we have developed for proving refinement and illustrates their usage on examples. Section 4 does the same for forward simulation. Finally, Section 5 discusses some related work, and Section 6 presents our conclusions and future plans.

2 Background

2.1 I/O Automata model

The formal model underlying TAME is the MMT automaton [11]. A general theory of Timed Input/Output Automata (TIOA) [8] for systems involving both discrete and continuous behavior has evolved since the inception of the MMT automaton. The TIOA model subsumes many other automata models, including the (untimed) I/O automaton model suitable for describing systems with only discrete events, the MMT automaton model, and the Alur-Dill timed automaton model [1]. Although the model used for the original development of the TAME was the MMT automaton, it will be possible to make the TAME templates and strategies work for a large and useful class of timed I/O automata with minor changes (see [6] for a report on ongoing work in this direction). Therefore, in this paper, we refer to MMT timed automata simply as (timed) I/O automata. In the following paragraph we give a very brief overview of the I/O automaton framework. For a complete description
of the TIOA model and the related results, see [8].

The main elements of an I/O automaton $A$ are its set of states, determined by the values of a set of state variables; its set of (usually parameterized) actions that trigger state transitions; and its set of start states. An execution of an $A$ is an alternating sequence of states and actions of $A$ in which the first state is an initial state of $A$ and each action in the sequence transforms its predecessor state into its successor state. For systems involving continuous evolution, a special time passage action records the changes in the continuous variables after an interval of time. The set of all possible behavior of $A$, then, is the set of all its executions. To define the notion of visible behavior, the actions of $A$ are partitioned into visible and invisible actions. The trace, or the externally visible behavior of $A$, corresponding to a given execution $\alpha$ is the sequence of visible actions in $\alpha$. In order to define the parallel composition operator on automata in a meaningful way, the visible actions are further partitioned into input and output actions. Since in the rest of this paper we reason only about individual automata (simple or explicitly composed) and not about component automata that are composed using the composition operator, for simplicity, we do not partition visible actions into input and output subsets.

2.2 TAME support for invariant proofs

State (or transition) invariants of an I/O automaton are properties that hold for all of its reachable states (or reachable transitions). To support proofs of invariants of an I/O automaton, TAME provides a template for specifying a (timed or untimed) I/O automaton, a set of standard PVS theories, and a set of strategies that embody the natural high-level steps typically needed in hand proofs of invariants. The standard PVS theories include generic theories such as machine, which establishes the principle of induction over reachable states, and special-purpose theories that can be generated from the DATATYPE declarations in an instantiation of the TAME automaton template. A sample of typical TAME steps for invariant proofs is shown in Figure 1.

2.3 Previous barriers to TAME support for abstraction proofs

Abstraction properties involve a pair of automata, and hence to express them generally, one needs a way to represent abstract automaton objects in PVS. The most convenient way to represent abstract automaton objects would be to make them instances of a type automaton. But, there are barriers to doing this in PVS. An I/O automaton in TAME is determined by instantiations of two types (actions and states), a set of start states, and a transition
relation. Abstractly, these elements can be thought of as fields in a record, and an abstract automaton object can be thought of as an instance of the corresponding record type. However, such a record type is not possible in PVS, because record fields in PVS are not permitted to have type “type”. An alternative way to express a type of automata would be to use create a polymorphic type automaton[α, σ] analogous to the polymorphic type (α, σ)ioa in [14]. However, unlike Isabelle/HOL, which was used in [14], PVS does not support parametric polymorphism.

Because no general automaton type can be defined in PVS, I/O automata are represented in TAME as theories obtained by instantiating the TAME automaton template. Invariants for I/O automata are based on the definitions in these theories. We will refer to instantiations of the TAME automaton template as TAME automata.

One possible way to support the definition of abstraction properties between two TAME automata is to create abstraction property templates that import two TAME automata (together with their associated invariants), and then require the user to tailor certain details of a definition of the abstraction property to match the details of the TAME automata. However, this approach is very awkward for the user, who must tailor fine points of complex definitions to specific cases and be particularly careful about PVS naming conventions. It is also awkward for the strategy-writer, whose strategies would need to make multiple probes in a standard property-definition structure to find details of the tailored definitions. Further, this scheme relies on the user adhering properly to a property template to permit a strategy to be reused in different instantiations of the property.
What is really needed is some means to define abstraction properties \textit{generically} in PVS. The design described in Section 2.4 provides such a means.

2.4 A new design for defining and proving abstraction in TAME

With the theory instantiation feature of PVS, together with other new PVS features, we have been able to design support for defining abstraction relations between two I/O automata that is both straightforward for a TAME user and clean from the point of view of the strategy developer. This support relies on (1) a new TAME supporting theory \texttt{automaton}, (2) a library of \textit{property theories}, and (3) new TAME templates for stating abstraction properties as theorems.

Figure 2 shows the theory \texttt{automaton}, which is an abstract declaration of the elements that specify an automaton. Other than the pattern of type restrictions, theory \texttt{automaton} makes no restrictions on the elements of its instantiations. In TAME, \texttt{automaton} is instantiated only with TAME automata. The names and types of elements in \texttt{automaton} match exactly the names and types of elements in the TAME automaton template. A new PVS feature allows the use of syntax matching to automatically extract the elements from a TAME automaton specification that instantiate elements of \texttt{automaton}, allowing the user to simply refer to the theory name of the TAME automaton as the instantiation for \texttt{automaton}; this relieves the user from the tedious effort of explicitly listing element instantiations. Because \texttt{states} and \texttt{actions} are both declared as \texttt{TYPE+}, i.e., nonempty types, instantiating \texttt{automaton} results in two TCCs (type correctness conditions) requiring these types to be nonempty.

Instantiation of \texttt{automaton} by a TAME automaton provides concrete definitions of the \texttt{automaton}'s elements. The concrete definitions for the first six

\begin{verbatim}
automaton: THEORY
BEGIN
  actions: TYPE+;
  states: TYPE+;
  start(s:states):bool;
  visible(a:actions):bool;
  enabled(a:actions, s:states): bool;
  trans(a:actions, s:states):states;

  reachable(s:states):bool
  invisible_seq_trans(s1, s2:states):bool;
  time_seq_trans(s1,s2:states, t:real):bool;
END automaton
\end{verbatim}

Fig. 2. The new TAME supporting theory \texttt{automaton}
of these elements are written by the user when filling in the TAME automaton template to define a TAME automaton. The remaining three elements are the same for all TAME automata and are defined in the time_machine theory which is a part of the TAME library. The user does not have to redefine them for specific automata, because an appropriate instance of time_machine is imported in the TAME automaton template. In every instantiation of automaton by a TAME automaton, the elements of automaton have the following properties: The visible and start predicates define the set of externally visible actions and the set of start states, respectively. The enabled(a,s) function returns true if action a is enabled in state s; it returns false otherwise. The transition function trans(a,s) gives the poststate that results from applying action a on state s. The reachable predicate recursively defines the set of reachable states of the automaton. The predicate invisible_seq_trans(s1,s2) is true if and only if there exists a sequence of invisible actions that takes state s1 to s2. And time_seq_trans(s1,s2,t) is true if and only if there exists a sequence of invisible and time passage actions that takes s1 to s2 with a total time passage of t units.

Examples of property theories for weak refinement and forward simulation are shown in Figures 3 and 4. As an aid to understanding the PVS notation, we will define in English the more complex of these two properties: forward simulation. A relation r between the states of a concrete automaton C and an abstract automaton A is a forward simulation relation if (1) for every start state of C, there exists a start state of A such that the two states are related by r, and (2) for every reachable transition (s_C, a, s1_C) of C, if a state

```pvs
weak_refinement[ A, C : THEORY automaton, 
    actmap: [C.actions -> A.actions], 
BEGIN 
  1 weak_refinement_base: bool = 
    2 FORALL(s_C:C.states): (C.start(s_C) => A.start(r(s_C)));
  3 weak_refinement_step : bool = 
    4 FORALL(s_C:C.states, a_C:C.actions): 
      5 C.reachable(s_C) AND C.enabled(a_C,s_C) => 
        6 (C.visible(a_C) => 
          7 (A.enabled(actmap(a_C),r(s_C)) AND 
            8 r(C.trans(a_C,s_C)) = A.trans(actmap(a_C),r(s_C))) ) AND 
        9 (NOT C.visible(a_C) => 
          10 (r(s_C) = r(C.trans(a_C,s_C))) 
          11 OR (r(C.trans(a_C,s_C))= A.trans(actmap(a_C),r(s_C)))))) 
  12 weak_refinement: bool = weak_refinement_base & weak_refinement_step;
END weak_refinement
```

Fig. 3. The new TAME property theory weak_refinement
s_A is related to s_C, then there exists an action sequence σ of A that takes s_A to s3_A such that: (a) r(s1_C, s3_A), and (b) the visible part of σ is same as of a. In the definition of f_simulation_action in Figure 4 part (2) of this definition is broken into the three cases—a is a visible non-time-passage action, a is a time-passage action, and a is an invisible action—to simplify strategy development. We are building a library of property theories which include other commonly used abstraction relations such as homomorphism, refinement, backward simulation, etc.

```plaintext
forward_simulation[C, A : THEORY timed_automaton,
    actmap: [C.actions -> A.actions],
    r: [C.states, A.states -> bool]] : THEORY
BEGIN
  f_simulation_base: bool = FORALL(s_C): (C.start(s_C) => EXISTS(s_A): A.start(s_A) AND r(s_C,s_A));
  f_simulation_action: bool = FORALL(s_C, s1_C, s_A, a_C):
      (C.reachable(s_C) AND A.reachable(s_A) AND r(s_C,s_A) AND
      C.enabled(a_C,s_C) AND s1_C = C.trans(a_C,s_C)) =>
      (C.visible(a_C) AND (NOT C.nu?(a_C)) =>
       EXISTS (s1_A, s2_A, s3_A):
         A.invisible_seq_trans(s_A,s1_A) AND
         A.invisible_seq_trans(s2_A,s3_A) AND
         r(s1_C, s3_A) AND A.enabled(actmap(a_C),s1_A) AND
         A.trans(actmap(a_C),s1_A) = s2_A) AND
      (C.nu?(a_C) =>
       EXISTS (s3_A):
         A.time_seq_trans(s_A,s3_A,timeof(a_C)) AND
         r(s1_C, s3_A)) AND
      (NOT C.visible(a_C) =>
       EXISTS (s3_A):
         A.invisible_seq_trans(s_A,s3_A) AND
         r(s1_C, s3_A));
  forward_simulation: bool = f_simulation_base & f_simulation_action;
END forward_simulation
```

Fig. 4. The new TAME property theory forward_simulation

A particular instance of the TAME template for stating abstraction properties as theorems is the theory tip_abstraction shown in Figure 5. (Note that in PVS notation, lists of assignments between the end markers (# and #) denote a record value. In TAME, both states and the basic components of states are record values.) The theory tip_abstraction instantiates two copies—one for each of the abstract and the concrete automata—of the automaton theory, defines the action and state mappings between the two automata, and imports the relevant property theory with all the above as parameters.
3 Strategies for refinement proofs

In this section, we discuss strategies we have developed for proving weak refinements for timed and untimed I/O automata. Since having a weak refinement relation between the states of two automata is equivalent to having a refinement relation between the reachable states of the two automata, we will often simply refer to “refinement” in what follows. We illustrate the utility of these strategies by sketching the proof of the correctness of a tree based leader election protocol and a failure prone memory in a remote procedure call (RPC) module.

3.1 Design of the refinement strategy

Our main strategy for proving refinements, PROVE_REFINEMENT, is based on the weak_refinement property shown in Figure 3. The generic nature of the definition of the weak_refinement property allows us to define PROVE_REFINEMENT in such a way that it can be applied to an arbitrary refinement proof between any given pair of automata. This strategy is designed to perform much if not all of the work, for an arbitrary instantiation of the
weak_refinement template, of proving by induction that the mapping ref from the states of concrete automaton MC to the states of abstract automaton MA is a refinement. The overall structure of PROVE_REFINEMENT in terms of substrategies is shown in Figure 6. First, PROVE_REFINEMENT splits a refinement theorem into its base case and induction case (corresponding to weak_refinement_base and weak_refinement_step in Figure 3). The base case is delegated to a substrategy called SETUP_REF_BASE, which performs the standard steps needed in the base case, including skolemizing, applying PVS’s EXPAND to the definitions of start and ref, and making some minor simplifications. PROVE_REFINEMENT then probes to see if the base case can be discharged trivially. Next, PROVE_REFINEMENT turns over the induction branch to the substrategy SETUP_REF_INDUCT_CASES.

Fig. 6. The PROVE_REFINEMENT strategy and related substrategies.

The substrategy SETUP_REF_INDUCT_CASES splits up the induction step into individual subgoals for each of the action types in the actions datatype, and hands off these individual subgoals to the substrategy START_REF_INDUCTION_BRANCH, which performs skolemization and expands the definition of visible. As reflected in Figure 6, this yields different sets of subgoals for visible and invisible actions. For each invisible action, a single congruence subgoal is generated from the condition in lines 10-11 in Figure 3. For each visible action, two new subgoals: an enablement subgoal and a congruence subgoal, are generated from lines 7 and 8 in Figure 3, respectively.

Congruence subgoals concern the correspondence of poststates, and START_REF_INDUCTION_BRANCH applies substrategy DO_TRANS to them; this strategy just expands the transition definition and repeatedly simplifies. START_REF_INDUCTION_BRANCH handles the first (enablement) subgoal for visible actions by applying the START_ENABLEMENT_PROOF strat-
PROVE_REFINEMENT resolves most of the subgoals for simple base and action cases of refinement proofs. For the subgoals that are not resolved, the user must interact with PVS, using steps such as TAME’s APPLY_INV_LEMMA, INST_IN, SKOLEM_IN, TRY_SIMP, and so on. In the next section we introduce the Tree Identify Protocol (TIP), which will serve us as a case study for illustrating the operation of the above strategies.

3.2 Refinement for correctness of the TIP algorithm

The TIP algorithm is a part of IEEE 1394 Firewire standard [4] and has been used as a case study for many different formal verification approaches. The TIP leader election protocol is invoked after a bus reset in the network (i.e. when a node is added to, or removed from, the network). Immediately after a bus reset all nodes in the network have equal status, and know only to which nodes they are directly connected. A leader needs to be chosen to act as the manager of the bus for subsequent operations. The TIP algorithm “grows” a directed spanning tree by means of parent-request messages sent from nodes to connected nodes until a root (the leader) of the tree is identified. Contention may arise when two nodes simultaneously send parent-requests to each other, and it is broken by nondeterministic back-off and retry. Following the authors of [4], we model the TIP algorithm as an untimed I/O automaton TIP which performs all the operations of the algorithm (sending parent-request messages, breaking contention, etc.) through invisible actions, and triggers its only visible action root only when a leader is identified.

For correctness, the TIP automaton must satisfy two properties: (a) at any given point in time there is at most one leader, and (b) in any execution at most one leader is ever elected, i.e., the root action occurs only once. Property (a) is an invariant of TIP and has been proved both directly in PVS by the authors of [4] and in TAME [3]. Property (b) is not an invariant, but it is captured by the executions of the simple automaton SPEC from [4]. The SPEC automaton has only one action: a visible action called root that is disabled after its first occurrence. By proving a that there exists a refinement from TIP to SPEC, we establish that all traces of TIP are included in the set of traces of SPEC, which in turn proves property (b).

Figure 5 shows our refinement template instantiated with the automata TIP and SPEC. The tip_abstraction theory in Figure 5 imports the library
theory weak_refinement (Figure 3) with four parameters. The parameters MA and MC are instantiations of the automaton theory corresponding to the SPEC and the TIP automata; amap is a map from the actions of TIP to the actions of SPEC, and ref is the refinement map from the states of TIP to the states of SPEC. As a result of this importing, the weak_refinement relation between TIP and SPEC is defined, and hence the corresponding refinement theorem tip_refinement_thm can be stated.

3.3 Applying the refinement strategy in the TIP case study

For the TIP example, PROVE_REFINEMENT divides the proof of tip_refinement_thm into the base case and the induction step. The base case sequent, which is handled by SETUP_REF_BASE, is shown in Figure 7, in which TIP_decl.start and SPEC_decl.start are the start predicates of TIP and SPEC, respectively. The induction step is split up into six branches by START_ENABLEMENT_PROOF, one for each of the six action subtypes in the TIP_decl.actions datatype. Corresponding to each visible action, two subgoals, for enablement and congruence, are generated. Figures 8 and 9 show the two subgoals generated for the (visible) nu action in TIP.

```plaintext
Fig. 7. Initial base case sequent for tip_abstraction.

Fig. 8. Initial enablement sequent for the action nu in TIP.
```

As seen in the saved proof for the TIP case study (Figure 10) all but two parts of the inductive goal for the root action—the specific enablement subgoal and the congruence subgoal—were resolved by this strategy automatically. Proving the root specific enablement subgoal required using two
invariant properties of TIP (invariants 13 and 15 from [4]), proved earlier with TAME. (Informally, invariant 13 says that a root node has the property that all its edges connect it to its children, and invariant 15 says that at most one node has this property.) The root congruence subgoal required INST. The root specific enablement and congruence subgoals both required the TAME “it is now trivial” step TRY_SIMP (see Figure 1) to complete.

In the interaction of PROVE_REFINEMENT and its substrategies, signif-
icant use is made of formula labels, both for deciding which action to take based on the presence or absence of a formula with a given label, and to focus computation on formulae with specific labels. The labels are designed to be informative: for example, the label `specific-precondition` on line 4 of the proof in Figure 10 belongs to the specific precondition of the root action of the abstract automaton (in this case, `SPEC`). This is so that when an unresolved subgoal is returned to the user, its content is as informative as possible. For the same reason, `PROVE_REFINEMENT` and its substrategies attach comments to any subgoals they create that denote their significance. The comment `specific enablement` that appears on line 2 in Figure 10 indicates that this subgoal is the specific enablement subgoal for the action root. The argument to root, `rootV_C_action`, is a skolem constant (automatically generated by `PROVE_REFINEMENT`) for the formal parameter `rootV` of root; its suffix `_C_action` indicates that it is generated from an action of the concrete automaton (in this case, `TIP`). Thus our new strategy `PROVE_REFINEMENT` adheres to the same design principles as the earlier TAME strategies (see [2]).

3.4 Applying the refinement strategy in the RPC case study

Our second case study for refinement proofs concerns the specification and implementation of the memory component of a remote procedure call (RPC) module taken from [16]. A failure prone memory component `MEM` and a reliable memory component `REL_MEM` are modeled as I/O automata, and the requirement is to show that every trace of `REL_MEM` is a trace of `MEM`. The `MEM` and `REL_MEM` automata are almost identical, except that the failure action in `MEM` is absent in `REL_MEM`. Owing to this similarity, the refinement map `ref` is a bijection and the action map `amap` is an injection. As noted in [16], a weak refinement from `REL_MEM` to `MEM`, suffices to establish trace inclusion. We state this weak refinement property by instantiating the weak refinement property theory template in a manner analogous to that in the `TIP/SPEC` example. In the proof in this case, all but the base case and one of the induction branches were resolved automatically by `PROVE_REFINEMENT`, and these remaining goals were easily discharged with `TRY_SIMP`.

4 Strategies for forward simulation proofs

In this section, we present the strategies we have developed for proving forward simulations. We illustrate the application of these strategies by proving time bounds for a failure detector and for a two process race system.
4.1 Design of the forward simulation strategies

We have developed two generic strategies for aiding forward simulation proofs: \texttt{PROVE\_FWD\_SIM} and \texttt{FWD\_SIM\_ACTION\_REC}. These strategies use new sub-strategies together with some of the substrategies discussed in the previous section. \texttt{PROVE\_FWD\_SIM} is similar to \texttt{PROVE\_REFINEMENT} in that it first breaks down a forward simulation theorem (Figure 4) into its base case and induction step, and then splits the induction step into cases for the individual action subtypes of the concrete automaton. The \texttt{FWD\_SIM\_ACTION\_REC} strategy is meant to be applied to the individual action branches produced by \texttt{PROVE\_FWD\_SIM}; it is used to prove the \texttt{A.invisible\_seq\_trans} or the \texttt{A.time\_seq\_trans} predicates (see Section 2.4) in the individual action branches. This strategy takes an action sequence $\sigma = a_1, a_2, \ldots, a_n$, a starting state $s_1$, and a known target state $s_2$, and produces the following set of subgoals:

- $s_2 = \text{trans}(a_n, \text{trans}(a_{n-1}, \text{trans}(a_{n-2}, \ldots, \text{trans}(a_1, s_1)\ldots)))$,
- For each action $a_i$ in $\sigma$, $a_i$ is not \text{visible}, and
- For each $i \in 1, \ldots, n$, $a_i$ is \text{enabled} in $\text{trans}(a_{i-1}, \text{trans}(a_{i-2}, \ldots, s)\ldots)$.

The strategy then discharges some of these subgoals by expanding definitions (e.g., \text{visible} and \text{enabled}) and then simplifying. The remaining non-trivial subgoals are then presented to the user with properly labeled sequents. To illustrate the details of operation of these strategies, we next present another case study: a failure detector algorithm.

4.2 Proving a time bound in a failure detector

This case study uses a forward simulation relation to prove the time bound of a failure detector taken from \cite{8}. The failure detector implementation consists of three components: (1) a sending process $P$ which sends a heartbeat message every $u_1$ time units as long as it has not failed, (2) a timed channel $C$ which delivers to $T$ each of the messages sent by $P$ within $b$ time units after it is sent, and (3) a timeout process $T$ which performs a timeout action if it does not receive any message over a time interval longer than $u_2$ units. The sending process $P$ fails when an externally controlled fail action occurs and stops sending the messages. As a result of the timeout action, the process $T$ suspects $P$ to have failed. The implementation is modeled as an automaton called \texttt{TIMEOUT} with the two visible actions \text{timeout} and \text{fail}.

Assuming $u_2 > u_1 + b$, we are interested in proving two properties: (a) safety: $T$ suspects $P$ implies that $P$ has really failed, and (b) timeliness: if $P$ fails then it is suspected by $T$ within $b + u_2$ time units. The safety property (a) is an invariant of \texttt{TIMEOUT}, and can be proved using the invariant strategies of TAME. The timeliness property (b) is modeled as a simple specification
automaton $TO\_SPEC$ which has just two actions, $\text{fail}$ and $\text{timeout}$, in addition to the time passage action. The automaton $TO\_SPEC$ simply triggers a $\text{timeout}$ action within $u_2 + b$ time units of the occurrence of a $\text{fail}$ action. To show that $TIMEOUT$ implements $TO\_SPEC$, we proved that the relation $\text{rel}$ between $TIMEOUT$ and $TO\_SPEC$ defined in Figure 11 is a forward simulation relation. In this definition, $TIMEOUT$ is represented by $MC$, $TO\_SPEC$ is represented by $MA$, $last\_timeout$ is the deadline for the $\text{timeout}$ action of $TO\_SPEC$, $last\_deadline$ is the deadline for the delivery of the last message in the channel, and $t\_clock$ is the deadline for timing out when no interim message is received.

4.3 Applying forward simulation strategies to $TIMEOUT$

For proving the $TIMEOUT/TO\_SPEC$ simulation property, we applied the $\text{PROVE\_FWD\_SIM}$ strategy to the forward simulation theorem. This application produces a base case subgoal and one subgoal for each of the five actions of $MC$: $\text{nu}$, $\text{send}$, $\text{receive}$, $\text{fail}$, and $\text{timeout}$. The Base case is handled by $\text{SETUP\_REF\_BASE}$. For each action $a$ of $MC$, the subgoals produced by $\text{PROVE\_FWD\_SIM}$ correspond to proving that the relation $\text{rel}$ is preserved, that is (in the notation used in the forward simulation property theory in Figure 4 on page 8), (1) there exists an action sequence of $MA$ starting from $s_A$ that leads to the state $s_3A$, and (2) given that $\text{rel}(s_C, s_A)$ holds, $\text{rel}(s_1C, s_3A)$ also holds. The second subgoal is common to all actions, but the subgoals produced for proving (1) depend on the type of the action $a$. For example, the time passage action $\text{nu}$ produces a $\text{time\_seq\_trans}$ subgoal (see Figure 12), the invisible action $\text{send}$ produces an $\text{invisible\_seq\_trans}$ subgoal, and the visible action $\text{timeout}$ produces two $\text{invisible\_seq\_trans}$ subgoals and two additional subgoals to show that the $\text{timeout}$ action of $MA$ takes $s_1A$ to $s_2A$. 

\begin{verbatim}
MC: THEORY = automaton :-\rightarrow TIMEOUT_decls
MA: THEORY = automaton :-\rightarrow TO\_SPEC_decls
rel(s_C: MC.states, s_A: MA.states):bool =
  failed(s_C) = failed(s_A) AND
  suspected(s_C) = suspected(s_A) AND
  now(s_C) = now(s_A) AND
  IF (not failed(s_A))
    THEN inftime?(last_timeout(s_A))
    ELSE IF nonemptyqueue?(queue(s_C))
      THEN last_timeout(s_A) >= last_deadline(s_C) + u_2
    ELSE last_timeout(s_A) >= t_clock(s_C)
  ENDIF
ENDIF
ENDIF
\end{verbatim}

Fig. 12. Sequents produced by PROVE_FWD_SIM for the time passage action nu, invisible action send, and visible action timeout.

For each action, showing that the post-states are related means that we have to show that the four conjuncts in rel are satisfied. This leads to four subgoals in each action branch. Some of these subgoals are trivial; others require the application of some previously proved invariants. The last subgoal requires us to prove inequalities involving real expressions; for this, we have
found the Field [13] and the Manip [5] strategy packages to be useful.

4.4 Proving time bounds for two process race

The second case study in which we applied our strategies to prove time bounds through a forward simulation relation is the two process race system described in [10], which we will call RACE. The automaton RACE models two processes running in parallel. The process main updates the counter or produces a report action within every time interval \([a_1, a_2]\). The second process produces a set action within the time interval \([b_1, b_2]\). The counter is initially set to zero, and it is incremented by main until the occurrence of the set action, from which point onward, the counter is decremented. Once the main process counts down to zero a report action is triggered.

The property of interest here is the upper and lower time bounds on the occurrence of the report action. The upper bound is given by \(b_2 + a_2 + b_2a_2/a_1\). The intuition behind this bound as follows: in order to maximize the value of the counter until the set action occurs, the main process should increment counter every \(a_1\) time. Thus, the value of counter when the set action occurs is \(b_2/a_1\). Thereafter, the maximum time taken to decrement counter down to zero is \(a_2b_2/a_1\). The latest time when the set action occurs is \(b_2\), and therefore the upper time bound for report is \(a_2 + b_2 + a_2b_2/a_1\). Reasoning similarly, one can show that the lower bound for the report action is \(b_1 + (b_1 - a_2)a_1/a_2\) if \(a_2 < b_1\), and \(a_1\) otherwise. These time bounds on report are specified as a simple abstract automaton RACE_SPEC which triggers a report action within the above time bounds.

The forward simulation relation rel used to prove that RACE implements RACE_SPEC is shown in Figure 13. In the definition of rel, first_action and last_action denote the lower and the upper bounds on the time of occurrence of action, respectively. This simulation relation is more complex than that for the TIMEOUT/TO_SPEC example because (a) it captures both the upper and the lower time bounds, and (b) the relation between the states differs depending on whether or not flag has been set by the set action. The structure of the proof is similar to that in the TIMEOUT/TO_SPEC example, and so our high level PROVE_FWD_SIM strategy successfully breaks up the simulation proof into subgoals for the individual actions. Applying FWD_SIM_ACTION_REC with the proper arguments instantiates and simplifies the action branches. Generally, each action branch leads to six subgoals corresponding to the six high level conjuncts in the simulation relation, but the trivial subgoals (e.g., first two subgoals) are discharged automatically by the strategy. The remaining subgoals required the application of previously proved invariants and reasoning about inequalities involving real expressions,
in which we found the Field and the Manip strategies to be useful.

5 Related work

A metatheory for I/O automata, based on which generic definitions of invariant and abstraction properties are possible, has been developed in Isabelle by Müller [14], who also developed an associated verification framework. Example proofs of forward simulation have been done for at least simple example automata using this framework; it is not clear to what extent uniform Isabelle tactics are employed. PVS has been used by others to do abstraction proofs, and in fact a refinement proof for TIP and SPEC was mechanized by Devillers et al. [4]. However, to our knowledge, no one has developed "generic" PVS strategies to support proving abstraction properties with PVS.

Our work is related to the tools being developed for the TIOA project [7,6]. The TIOA to PVS translator, which is currently under development, produces PVS specifications of timed (or untimed) I/O automata in the style described in this paper. The translator and our strategies are designed to mask the details of the PVS theorem prover, so that the user can specify a TIOA and prove its properties in PVS without learning the details of the PVS language and prover.

6 Conclusions and future work

We have developed supporting PVS theories and templates for abstraction proof strategies, and added them to TAME. The supporting theories include
a set of abstraction property theories that are being collected into a library, and
generic automaton theories that serve as theory types for theory parameters to our
property theories. For each abstraction property theory, there is a
template to allow the abstraction property to be instantiated as a (proposed)
theorem that relates two particular automata. Building on this structure,
we have added both a reusable PVS weak refinement strategy and a reusable
forward simulation strategy to TAME, and have applied these strategies to
examples. In the example weak refinement proofs we have done so far, previously
existing TAME strategies provide sufficient proof steps for interactively com-
pleting the refinement proofs. While previously existing TAME proof steps
were useful in completing the forward simulation proofs, the TAME steps had
to be supplemented, for example with proof steps from the Field \cite{13} and
Manip \cite{5} strategy packages.

Our approach to developing strategies for abstraction proofs is geared towards
theorem provers that support tactic-style interactive proving. In theorem
proving systems that allow a definition of an automaton type, an approach
to developing such strategies that is not based on templates may be possible.
Because we cannot expect to develop strategies that will do arbitrary abstrac-
tion proofs fully automatically, a major goal for us is to design our strategies
to support user-friendly interactive proving. A PVS feature that facilitates
making both interaction with the prover and understanding the significance
of saved proofs easier is support for comments and formula labels. Thus, a
challenge for other theorem proving systems is to find ways to support ease
of understanding during and after the proof process equivalent to what we
provide using PVS.

As with any other product of a development project, our strategies will re-
quire more testing, tuning, and optimization after the initial conceptual phase
of development whose results we have described in this paper. We have begun
work on developing new strategies useful for (interactively) completing proofs
of action cases. Much of this is currently being undertaken within the TIOA
project. We also plan to add proof support for other abstraction properties
and to continue adding new strategies for interactive proof completion.

Acknowledgements

We thank Sam Owre and Natarajan Shankar of SRI International for adding
the features to PVS that have made our work possible. We also thank Nancy
Lynch and Dilsun Kaynar for useful discussions on the case studies. Finally,
we thank the anonymous reviewers for many helpful suggestions on improving
this paper.
